WIND SPEED ANALYSIS FOR LAKE OKEECHOBEE
by
Mingyan Hu

This thesis was prepared under the direction of the candidate's thesis advisor, Dr. Lianfen Qian, Department of Mathematical Sciences, and has been approved by the members of her supervisory committee. It was submitted to the faculty of The Charles E. Schmidt College of Science and was accepted in partial fulfillment of the requirements for the degree of Master of Science.

SUPERVISORY COMMITTEE:

Mathematical Sciences

Dean, Charles E. Schmidt College of Science

Vice Provost
Date

## ACKNOWLEDGMENTS

I would like to thank my advisor, Dr. Lianfen Qian, who spent a lot of time on advising my research work. I sincerely appreciate her for giving me the opportunity to work with her. Her rich knowledge, wise thoughts and kind guidance encouraged me to complete this research. I would like to thank Dr. Kangren Jin, for providing data set and suggestions. I would like to thank Dr. Jose Correa for agreeing to serve on my thesis committee. Special thanks also goes to Dr. Heinrich Niederhausen and Dr. Frederick Hoffman for reviewing my thesis. I would like to thank my husband Mr. Minqing Lu, for his support and understanding of my work. And I would like to thank my mother, MS. Xiuen Zhang and my mother-in-law, MS. Caixian Li, who helped me to take care of my two kids.

I also thank Meihui Mao, Kehan Gao and all my friends for their kind support.

## ABSTRACT

| Author: | Mingyan Hu |

| Title: | Wind Speed Analysis for Lake Okeechobee |
| Institution: | Florida Atlantic University |
| Thesis Advisor: | Dr. Lianfen Qian |
| Degree: | Master of Science |
| Year: | 2002 |

In this thesis, we analyze wind speeds collected by South Florida Water Management District at stations L001, L005, L006 and LZ40 in Lake Okeechobee from January 1995 to December 2000. There are many missing values and outliers in this data. To impute the missing values, three different methods are used: Nearby window average imputation, Jones imputation using Kalman filter, and EM algorithm imputation. To detect outliers and remove impacts, we use ARIMA models of time series. Innovational and additive outliers are considered. It turns out that EM algorithm imputation is the best method for our wind speed data set. After imputing missing values, detecting outliers and removing the impacts, we obtain the best models for all four stations. They are all in the form of seasonal $\operatorname{ARIMA}(2,0,0) \times(1,0,0)_{24}$ for the hourly wind speed data.

## Chapter 1

## INTRODUCTION

Lake Okeechobee (Figure 1.1) is a natural lake in South Central Florida. Its name comes from two Indian words and means "big water". It is the second largest natural lake in the United States of America and is located at 27 N Latitude and 80 W Longitude. Its surface area is approximately $1730 \mathrm{~km}^{2}$. It is very shallow, with mean and maximum depths of 2.7 m and 5.5 m , respectively. A flood control dike built between 1930 and 1960 encircled the natural lake [12]. Currently, the lake has a storage capacity of about 40 billion cubic meters of water. Water levels are regulated according to a schedule developed by the U.S. Army Corps of Engineers. In addition to providing regional flood control, primary uses of the lake include agricultural water supply, drinking water for lakeside cities and towns and a backup water supply for the communities of the lower east coast of Florida. Other uses are commercial and recreational fishing, navigation and wildlife habitat. Lake Okeechobee is also a major component of the Kissimmee-Okeechobee-Everglades hydrologic system, receiving drainage from the Kissimmee River and discharging to the Everglades Agricultural Area [17].

Sample Sites: $16=\mathrm{L} 001,38=\mathrm{L} 005,39=\mathrm{L} 006,35=\mathrm{LZ} 40$

Figure 1.1: Lake Okeechobee and Data Collection Sites

Lake Okeechobee wind speed data are routinely collected by sensors and transcribed from field/laboratory forms to an electronic format. The data set analyzed in this thesis is the wind speeds (miles per hour) collected at stations L001, L005, L006 and LZ40 (corresponding sample sites 16, 38, 39 and 35, respectively in Figure 1.1) from January 1995 to December 2000. From the exploratory data analysis in Chapter 2, we observed that the monthly means of wind speeds are around 8 mph in summer, while they are greater than 10 mph in all other seasons. The patterns of
wind speeds for all four stations are similar. But the monthly means of wind speeds at station L001 is substantially different from those of the other stations in September 1995 and February 1998, and there are more missing values at station L001 than at other stations. In 1995, the monthly means at station L001 are obviously less than those of other stations. This little difference at station L001 may be caused by various reasons, such as location of the station, device failures or bird interruptions. The wind speeds of the four stations are correlated positively. In an attempt to explain the distribution of the data in a three-parameter Weibull distribution, the goodness of fit tests in Table 2.7 show that the distribution does not fit well. A possible improvement may be to use a lognormal, beta or mixed distribution.

Since there are lots of missing values in this data set, we have to impute the missing values before we detect outliers. In this thesis, we use three imputation methods: Nearby window average imputation, Jones imputation using Kalman filter [13] and EM algorithm imputation [19]. In Chapter 3, we introduce the three methods.

The effects of extraneous objects, measuring device failures and human errors may distort the field data. Usually qualified engineers, scientists or technicians identify abnormalities after inspecting the data manually. This manual process is slow, costly and sometimes inconsistent among inspectors [12]. Various methods, such as artificial intelligence [8], neural network [12] and outlier detection in time series models, have been used for detecting abnormal data. In Chapter 3, we also use

Figure 1.2: Flow Chart of Modeling Process
time series analysis to detect and remove the abnormal data. A common approach to deal with outliers in a time series is to identify the locations, and the types of outliers and then remove the impacts by using intervention models. Four types of outliers are usually considered: Innovational outlier (IO), additive outlier (AO), level shift (LS) and temporary change (TC) [20]. For the wind speed data, the outliers could be either IO or AO. Hence, only IO and AO are considered in this thesis. We also studied the power of three imputation methods by using a small portion of time series from station L001. Based on the results, we use EM algorithm to impute missing values for the data set used in this thesis.

To get the best model for the wind speed data, the idea is shown in Figure
1.2. After imputing the missing values and removing the impacts of outliers, we can get the best model. This is presented in Chapter 4. Due to the computing problem, the data set used in Chapter 4 is the hourly wind speeds of all four stations from May to August in 2000 only. The best models are seasonal ARIMIA(2, 0, 0) $\times(1,0,0)_{24}$ for all four stations. The term $(2,0,0)$ gives the order of the nonseasonal part of the ARIMA model; the term $(1,0,0)_{24}$ gives the order of the seasonal part. The form of this model is given by

$$
\left(1-\phi_{1,1} B-\phi_{1,2} B^{2}\right)\left(1-\phi_{2,1} B^{24}\right) x_{t}=\mu+\epsilon_{t} \quad t=1, \cdots, n
$$

where n is the number of observations in the time series; $B$ is the backshift operator such that $B x_{t}=x_{t-1} ;\left(1-\phi_{1,1} B-\phi_{1,2} B^{2}\right)\left(1-\phi_{2,1} B^{24}\right)$ is a polynomial of $B$ with all roots outside the unit circle; $\left\{\epsilon_{t}\right\}$ is uncorrelated and identically distributed with mean zero and variance $\sigma^{2}$; The value 24 reflects a daily circle in the hourly wind speed data. Thus, it shows that the wind speed in all stations under study behaves similarly. This suggests that it is not necessary to collect data from all the stations under study.

In an appendix, we include the Matlab codes and SAS programs used for this thesis.

## Chapter 2

## DATA EXPLORATION

Lake Okeechobee wind speed data are routinely collected by sensors and transcribed from field/laboratory forms to an electronic format. Field data were collected every 15 minutes by the South Florida Water Management District (SFWMD) at a permanent data collection site (Figure 1.1, [11]). Wind speeds (miles per hour) were measured with a Skyvane Wind Sensor Model 2100. Occasionally the effects of extraneous factors such as birds, measuring device failures and human errors, may distort field data [12]. The data set analyzed in this thesis consists of the wind speeds collected at stations L001, L005, L006 and LZ40 (corresponding sample sites 16, 38, 39 and 35, respectively in Figure 1.1) from January 1995 to December 2000.

### 2.1 Station L001

Station L001 is in the north of Lake Okeechobee (Figure 1.1). Table 2.2 and Figure 2.1 show that the monthly means are between 8 mph and 13 mph except September 1995, July 1997 and February 1998. The monthly mean of wind speeds in July 1997 is missing because the wind speeds are all missing. Table 2.2 shows that there are 6 large values of maximum (bold) wind speed (wind speed that is 40 mph or

Figure 2.1: Plots of Monthly Mean Values for All Stations
above is considered as a large value). There are 21024 missing values at station L001 (Table 2.1). The number of missing values on September 1995 and February 1998 are 1302 and 2126 (Table 2.2) with missing rates $45.2 \%$ and $79 \%$, respectively. It is possible that the large number of missing values caused the unusual monthly means: 4.70 mph and 17.59 mph for September 1995 and February 1998, respectively. There are more missing values in 1997 and 1998 than in the other years on this station.

### 2.2 Station L005

Station L005 is in the west of Lake Okeechobee (Figure 1.1). Table 2.3 and Figure 2.1 show that all the monthly means are between 8 mph and 14 mph . There are 4 large values of maximum wind speeds which are greater than 40 mph . There are only 96 observed values on December 2000. The total number of missing values

is 849 (Table 2.1). There are many more missing values (467) on April 1996 than on any other months.

### 2.3 Station L006

Station L006 is in the south of Lake Okeechobee (Figure 1.1). Table 2.4 shows that the monthly means are between 8 mph and 14 mph . Figure 2.1 shows that there is no extreme monthly mean value. Table 2.4 shows that four values of

maximum wind speed are over 40 mph . There are 6270 missing values at this station
(Table 2.1). The number of missing values on November 1998, December 1998 and
August 2000 is more than 1000 (Table 2.4).

### 2.4 Station LZ40

Station LZ40 is in the middle of Lake Okeechobee (Figure 1.1). Table 2.5
shows that the monthly means are between 8 mph and 14 mph . Figure 2.1 shows

Table 2.5: Descriptive Statistics for LZ40

| Month | Obs | Miss | Mean | Min | Max | Month | Obs | Miss | Mean | Min | Max |

that there is no extreme monthly mean value. There are 7 values of maximum wind speed which are over 40 mph (Table 2.5). The total number of missing values is 7018 (Table 2.1). The number of missing values in April and October 1995, and August 1996 is more than 1000 (Table 2.5).

### 2.5 Using a Weibull Distribution to Describe Wind Speed

The Weibull distribution is usually used to describe wind speeds and study wind power. It is very practical for this application, because the distribution does not allow for negative values and it is easy to appropriately consider the fact that on most days there will be a bit of wind and on some days a lot.

The three-parameter Weibull distribution has probability density function given by

$$
f(y)=\frac{c}{\sigma}\left(\frac{y-\theta}{\sigma}\right)^{c-1} \exp \left(-\left(\frac{y-\theta}{\sigma}\right)^{c}\right) \quad \text { for } y>\theta, c>0, \sigma>0,
$$

where $\theta$ is the threshold parameter, $\sigma$ is the scale parameter and $c$ is the shape parameter [9]. The cumulative distribution function is given by

$$
F(y)=1-\exp \left(-\left(\frac{y-\theta}{\sigma}\right)^{c}\right) \text { for } y>\theta .
$$

The mean and variance are given by

$$
E(y)=\theta+\sigma \Gamma\left(1+\frac{1}{c}\right)
$$

and

$$
\operatorname{Var}(y)=\sigma^{2}\left[\Gamma\left(1+\frac{2}{c}\right)-\Gamma^{2}\left(1+\frac{1}{c}\right)\right]
$$

where $\Gamma$ is the gamma function. The mean wind speed is used to indicate how windy the site is. The shape parameter tells how peaked the distribution is; i.e., if the wind speeds always tend to be very close to a certain value, the distribution will have a high shape parameter value and will be very peaked.

Table 2.6: Exploratory Data Analysis

| Station | Mean | SD | Skew | Kurtosis | Q1 | Q2 | Q3 | $\max$ |
| ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| L001 | 10.214 | 5.549 | 0.420 | 0.731 | 6.358 | 10.050 | 13.740 | 72.400 |
| L005 | 10.479 | 5.404 | 0.513 | 0.576 | 6.577 | 10.050 | 14.010 | 56.260 |
| L006 | 11.056 | 5.702 | 0.611 | 0.543 | 6.960 | 10.540 | 14.570 | 49.950 |
| LZ40 | 11.041 | 5.722 | 0.629 | 0.609 | 6.831 | 10.536 | 14.590 | 55.680 |

To check if a Weibull distribution fits a data set well, we use the AndersonDarling test [18]. The hypotheses of the test are:
$H_{0}:$ the data follow Weibull distribution,
$H_{a}:$ the data do not follow Weibull distribution.

The test statistic is given by

$$
A^{2}=-n-S
$$

where $S=\sum_{i=1}^{n}\left(\ln F\left(y_{i}\right)+\ln \left(1-F\left(y_{n+1-i}\right)\right)\right), n$ is sample size, $y_{2}$ are ordered and $F$ is the cumulative distribution function.

The descriptive statistics for the 15 -minute wind speed data for the four stations are shown in Table 2.6. We can see that more than $75 \%$ of the wind speed data are below 15 mph . The means and standard deviations of Stations L006 and LZ40 are about the same and greater than those of Stations L001 and L005. The histograms in Figure 2.2 show that the distributions are skewed to the right. The maximum likelihood estimations of the parameters of the Weibull distribution are reported in Table 2.7 for all four stations. The p-values of Anderson-Darling

Table 2.7: Weibull Distribution Parameters and Goodness-of-Fit Tests

|  | Threshold |  |  |  |  |  |  |
| ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| Station | $(\theta)$ | Scale <br> $(\sigma)$ | Shape <br> $($ c $)$ | Mean | SD | Anderson-Darling <br> test statistic | p-value |
| L001 | -1.864 | 13.614 | 2.297 | 10.197 | 5.568 | 448.981 | $<0.001$ |
| L005 | -0.889 | 12.822 | 2.211 | 10.467 | 5.424 | 106.016 | $<0.001$ |
| L006 | -0.617 | 13.170 | 2.146 | 11.046 | 5.723 | 82.962 | $<0.001$ |

goodness-fit-test are all less than 0.001 . This means that a three-parameter Weibull distribution does not fit our wind speed data well. A possible suggestion will be to use a $\log$ normal, beta or mixed distribution.

### 2.6 Conclusion

Comparing the number of missing values in Table 2.1, there are much more missing values at station L001 than at any other station. Comparing plots of monthly means of wind speeds for all four stations (Figure 2.1), we can see that the patterns of the plots for station L005, L006 and LZ40 are similar. Hence we further check the correlations of wind speeds among these four stations. The Pearson product moment correlation coefficient of two variables is given by

$$
r=\frac{\sum_{i=1}^{n}\left(x_{i}-\bar{x}\right)\left(y_{i}-\bar{y}\right)}{(n-1) s_{x} s_{y}}
$$

where $n$ is the number of observations, $\bar{x}$ and $\bar{y}$ are sample means of two variables, and $s_{x}$ and $s_{y}$ are sample standard deviations of two variables, respectively. Table 2.8 shows Pearson correlations of wind speeds among the stations in 2000. All correlation coefficients are greater than 0.6 , and the p-values for the hypothesis

L005

LZ40

Figure 2.2: Histograms of Wind Speeds

Table 2.8: Correlations among Four Stations

| Station | L001 | L005 | L006 |
| ---: | ---: | ---: | ---: |
| L005 | 0.668 |  |  |
|  | $(<0.001)$ |  |  |
| L006 | 0.748 | 0.678 |  |
|  | $(<0.001)$ | $(<0.001)$ |  |
| LZ40 | 0.758 | 0.697 | 0.897 |
|  | $(<0.001)$ | $(<0.001)$ | $(<0.001)$ |
| Note: values in parentheses are p-values |  |  |  |

tests of the correlation coefficients being zero are less than 0.001 . Therefore, the wind speeds of the four stations are correlated positively.

The monthly means of wind speeds at station L001 is substantially different from those of any other stations on September 1995 and February 1998, and there are more missing values at station L001 than at other stations. In 1995, the monthly means at station L001 are obviously less than at any other station. This little difference at station L001 may be caused by various reasons such as location of the station, measuring device failures or bird interruptions. Further detection is needed. To check the large values of maximum wind speeds (i.e. gerater than 40 mph ) for all stations, we compared the maximum wind speeds at all stations for the months that have large values. Table 2.9 shows that there are large values on October 1999 at all stations. There was a hurricane named Floyd on October 1999. At station L001, the maximum wind speeds on April 1997, July 1998, August 1998 and October 1998 are obviously much higher than those at the other stations. In Figure 2.3, one can

Table 2.9: Large Values for All Stations

| Time | L001 | L005 | L006 | LZ40 |
| :---: | :---: | :---: | :---: | :---: |
| 07/96 | 30.87 | 32.81 | 38.34 | *40.75 |
| 04/97 | *63.59 | 34.61 | 30.88 | 32.61 |
| 05/97 | 24.7 | *45.39 | 26.19 | *41.42 |
| 06/97 | 22.27 | 27.66 | *41.34 | *40.98 |
| 02/98 | *40.66 | 37.54 | 37.89 | 37.67 |
| 07/98 | *68.1 | 32.16 | 34.22 | 31.35 |
| 08/98 | *58.6 | 34.11 | 34.98 | 33.99 |
| 10/98 | *72.4 | 25.81 | 31.28 | 30.73 |
| 11/98 | 37.45 | 35.93 | *40.89 | *40.59 |
| 05/99 | 29.36 | 35.94 | *40.29 | 35 |
| 10/99 | *55.13 | *45.91 | *49.95 | *55.68 |
| 08/00 | 31.13 | 26.11 | *42 | 30.02 |
| 10/00 | 29.86 | *52.13 | 36.12 | 34.32 |
| 11/00 | 26.55 | *56.26 | 34.93 | *49.3 |
| 12/00 | 35.09 | 17.09 | 36.42 | *42.6 |

see that those four points $(63.59,68.1,58.6$ and 72.4$)$ are outlier points, which might be affected by local climate or extraneous factors.

Finaly, we conclude that there are outliers and many missing values in the data sets. The patterns of wind speeds for all four stations are similar and the wind speeds of these four stations are correlated positively. We also observed that for the four stations the monthly means of wind speeds are around 8 mph in summer while they are greater than 10 mph in all other seasons. The monthly means of wind speeds at station L001 are substantially different from those of the other stations on September 1995, February 1998 and in 1995. There are more missing values at station L001 than at other stations. A three-parameter Weibull distribution does

Figure 2.3: Plots of Possible Outliers at Station L001
not fit this data well, as is seen by checking the goodness of fit tests in Table 2.7.
A possible improvement may be to use a lognormal, beta or mixed distribution.

## Chapter 3

## MISSING VALUE IMPUTATION AND OUTLIER DETECTION

As pointed out in Chapter 2, there are many missing values and outliers in the wind speed data. Let $x_{t}$ be the true time series, $y_{t}$ be the observed series with missing values and outliers, and $z_{t}$ be the observed series with outliers after imputation. Thus, we impute the missing values and then detect outliers. In this thesis, three imputation methods are used: Nearby window average imputation, Jones imputation using Kalman filter [13] and EM algorithm imputation [19]. Two types of outliers are considered in this thesis: Innovational outlier (IO) and additive outlier (AO) [20].

### 3.1 Missing Value Imputation

Nearby window average imputation, Jones imputation using Kalman filter and EM algorithm imputation are used to impute missing values. The idea of the Nearby window method is to use the average value of one value before the missing
value begins and one value after the missing value ends to impute the missing values. The other two methods are introduced in the following.

### 3.1.1 Imputation Using Kalman Filter

Richard H. Jones considered a state-space model using Fialman recursive estimation for time series data with missing values in 1980. Here we only introduce state-space model and Kalman filter (see [13] for details).

### 3.1.1.1 State-space Model and Kalman Recursive Estimation

A State-space model has two equations: the observation equation and the state equation. Let $y_{t}$ be an observed time series. Then the observation equation is given by

$$
\begin{equation*}
y_{t}=H \theta_{t}+\nu_{t} \tag{3.1}
\end{equation*}
$$

where $H$ is a $(1 \times m)$ vector, $\theta_{t}$ is a $(m \times 1)$ state vector, and $\nu_{t}$ denotes the observation error. The $\nu_{t}$ 's are assumed to be uncorrelated and identically distributed with mean zero and variance $R$. Although the state vector $\theta_{t}$ is unobservable, we can assume that it follows the state equation

$$
\begin{equation*}
\theta_{t}=G \theta_{t-1}+w_{t} \tag{3.2}
\end{equation*}
$$

where $G$ is assumed to be a known $(m \times m)$ matrix. The term $w_{t}$ denotes a vector of deviates, which is white noise with zero mean vector and known variance-covariance matrix $Q$, and is assumed to be uncorrelated with $\nu_{t}$.

Assuming that the best unbiased estimator for $\theta_{t-1}$ is $\hat{\theta}_{t-1}$ based on our knowledge about the process prior to time $t-1$, the variance-covariance matrix of $\hat{\theta}_{t-1}$ is $P_{t-1}$. Let $\hat{\theta}_{t \mid t-1}$ be the one-step ahead forecast of $\theta_{t}$ from time $t-1$, i.e.

$$
\begin{equation*}
\hat{\theta}_{t \mid t-1}=G \hat{\theta}_{t-1} \tag{3.3}
\end{equation*}
$$

Then the estimation error is

$$
\begin{aligned}
e_{t \mid t-1} & =\theta_{t}-\hat{\theta}_{t \mid t-1} \\
& =G \theta_{t-1}+w_{t}-G \hat{\theta}_{t-1} \\
& =G\left(\theta_{t-1}-\hat{\theta}_{t-1}\right)+w_{t}
\end{aligned}
$$

and the associated error covariance matrix is

$$
\begin{align*}
P_{t \mid t-1} & =E\left[e_{t \mid t-1} e_{t \mid t-1}^{\prime}\right]  \tag{3.4}\\
& =G \operatorname{Var}\left(\hat{\theta}_{t-1}\right) G^{\prime}+\operatorname{Var}\left(w_{t}\right)  \tag{3.5}\\
& =G P_{t-1} G^{\prime}+Q \tag{3.6}
\end{align*}
$$

where $e_{t \mid t-1}^{\prime}$ is the transposition of $e_{t \mid t-1}$. If $y_{t}$ is available, then we may use the observed $y_{t}$ to improve the estimate of $\theta_{t}$. Let $\hat{\theta}_{t}$ be the updated estimate of $\theta_{t}$ satisfying the following equation:

$$
\begin{equation*}
\hat{\theta}_{t}=\hat{\theta}_{t \mid t-1}+K_{t}\left(y_{t}-H \hat{\theta}_{t \mid t-1}\right), \tag{3.7}
\end{equation*}
$$

where $K_{t}$ is called the Kalman gain [21]. The reason for constructing this $\hat{\theta}_{t}$ is to minimize the variance of the prediction error $e_{t} \equiv \theta_{t}-\hat{\theta}_{t}$. To derive $K_{t}$ we use the
minimum mean-square error criterion [3]. From (3.1) and (3.7), the error covariance matrix associated with the updated estimate is

$$
\begin{aligned}
P_{t} \equiv & E\left[e_{t} e_{t}^{\prime}\right]=E\left[\left(\theta_{t}-\hat{\theta}_{t}\right)\left(\theta_{t}-\hat{\theta}_{t}\right)^{\prime}\right] \\
= & E\left[\left(\theta_{t}-\hat{\theta}_{t \mid t-1}-K_{t}\left(H \theta_{t}+\nu_{t}-H \hat{\theta}_{t \mid t-1}\right)\right)\left(\theta_{t}-\hat{\theta}_{t \mid t-1}-K_{t}\left(H \theta_{t}+\nu_{t}-H \hat{\theta}_{t \mid t-1}\right)\right)^{\prime}\right] \\
= & E\left[\left(e_{t \mid t-1}-K_{t}^{\prime}\left(H e_{t \mid t-1}+\nu_{t}\right)\right)\left(e_{t \mid t-1}-K_{t}^{\prime}\left(H e_{t \mid t-1}+\nu_{t}\right)\right)^{\prime}\right] \\
= & E\left[e_{t \mid t-1} e_{t \mid t-1}^{\prime}-e_{t \mid t-1} e_{t \mid t-1}^{\prime} H^{\prime} K_{t}^{\prime}-e_{t \mid t-1} \nu_{t}^{\prime} K_{t}^{\prime}\right. \\
& -K_{t} H e_{t \mid t-1} e_{t \mid t-1}^{\prime}+K_{t} H e_{t \mid t-1} e_{t \mid t-1}^{\prime} H^{\prime} K_{t}^{\prime}+K_{t} H e_{t \mid t-1} \nu_{t}^{\prime} K_{t}^{\prime} \\
& \left.-K_{t} \nu_{t} e_{t \mid t-1}^{\prime}+K_{t} \nu_{t} e_{t \mid t-1}^{\prime} H^{\prime} K_{t}^{\prime}+K_{t} \nu_{t} \nu_{t}^{\prime} K_{t}^{\prime}\right] \\
= & P_{t \mid t-1}-P_{t \mid t-1} H^{\prime} K_{t}^{\prime}-K_{t} H P_{t \mid t-1}+K_{t} H P_{t \mid t-1} H^{\prime} K_{t}^{\prime}+K_{t} R K_{t}^{\prime}
\end{aligned}
$$

Rewrite the error covariance matrix associated with the updated estimate in the form:

$$
\begin{equation*}
P_{t}=P_{t \mid t-1}-P_{t \mid t-1} H^{\prime} K_{t}^{\prime}-K_{t} H P_{t \mid t-1}+K_{t}\left(H P_{t \mid t-1} H^{\prime}+R\right) K_{t}^{\prime} \tag{3.8}
\end{equation*}
$$

Differentiate the trace of $P_{t}$ with respect to $K_{t}$. By the facts that

$$
\begin{gathered}
\frac{d[\operatorname{trace}(A B)]}{d A}=B^{\prime}(\mathrm{AB} \text { must be square }) \\
\frac{d\left[\operatorname{trace}\left(A C A^{\prime}\right)\right]}{d A}=2 A C(\mathrm{C} \text { must be square })
\end{gathered}
$$

and

$$
\operatorname{trace}\left(P_{t \mid t-1} H^{\prime} K_{t}^{\prime}\right)=\operatorname{trace}\left(K_{t} H P_{t \mid t-1}\right)
$$

we have

$$
\begin{equation*}
\frac{d\left(\operatorname{trace} P_{t}\right)}{d K_{t}}=-2\left(H P_{t \mid t-1}\right)^{\prime}+2 K_{t}\left(H P_{t \mid t-1} H^{\prime}+R\right) \tag{3.9}
\end{equation*}
$$

Figure 3.1: Kalman Recursive Process
Setting (3.9) to be zero and solving for $K_{t}$, we get

$$
\begin{equation*}
K_{t}=P_{t \mid t-1} H^{\prime}\left(H P_{t \mid t-1} H^{\prime}+R\right)^{-1} \tag{3.10}
\end{equation*}
$$

From (3.8) and (3.10), we have

$$
\begin{equation*}
P_{t}=P_{t \mid t-1}-K_{t} H P_{t \mid t-1} . \tag{3.11}
\end{equation*}
$$

Equations (3.3), (3.4), (3.7), (3.10) and (3.11) are the Kalman filter recursive equations. The Kalman recursive process is shown in Figure 3.1.

### 3.1.1.2 State-space Model Representations of ARMA and ARIMA Models

Let $x_{t}$ be a time series following an autoregressive-moving average (ARMA) model with order $(p, q)$, i.e.,

$$
\begin{equation*}
\phi(B) x_{t}=\psi(B) \epsilon_{t} \quad t=1, \cdots, n \tag{3.12}
\end{equation*}
$$

where n is the number of observations in the time series; $B$ is the backshift operator such that $B x_{t}=x_{t-1} ; \phi(B)=1-\phi_{1} B-\cdots-\phi_{p} B^{p}$ and $\psi(B)=1-\psi_{1} B-\cdots-\psi_{q} B^{q}$ are polynomials of $B$ with all roots outside the unit circle; $\left\{\epsilon_{t}\right\}$ is white noise with mean zero and variance $\sigma^{2}$. Let $y_{t}$ still be an observed time series. Define the state vector of this process as

$$
\theta_{t}=\left[\begin{array}{c}
x(t \mid t) \\
x(t+1 \mid t) \\
\vdots \\
x(t+m-1 \mid t)
\end{array}\right]
$$

where $m=\max (p, q+1), x(t \mid t)=x_{t}$ and $x(t+1 \mid t)$ is the projection of $x_{t+j}$ on the values of the times series up to time $t$. Then the observation equation is

$$
y_{t}=\left[\begin{array}{llll}
1 & 0 & \cdots & 0 \tag{3.13}
\end{array}\right] \theta_{t}+\nu_{t}
$$

where $\nu_{t}$ is the observational error, uncorrelated at different times and uncorrelated with the $\epsilon$ 's. The mean of $\nu_{t}$ is 0 and its variance is $R=E\left[\nu_{t}\right]^{2}$. The state equation
is

$$
\begin{equation*}
\theta_{t+1}=G \theta_{t}+A \epsilon_{t+1}, \tag{3.14}
\end{equation*}
$$

where

$$
G=\left[\begin{array}{ccccc}
0 & 1 & 0 & \cdots & 0 \\
0 & 0 & 1 & \cdots & 0 \\
& & \vdots & & \\
\phi_{m} & \phi_{m-1} & \cdots & \phi_{2} & \phi_{1}
\end{array}\right]
$$

$\phi_{i}=0$ for $i>p ; A=\left[1, a_{2}, \cdots, a_{m}\right]^{\prime} ; a_{1}=1, a_{j}=-\psi_{j-1}+\sum_{i=1}^{j-1} \phi_{i} a_{j-i}$ for $j>1$ and $\psi_{j}=0$ for $j>q$ (See [13] for details).

For the ARMA model, the likelihood for $n$ observations of the zero mean process is

$$
\begin{equation*}
L=\prod_{t=1}^{n}\left(2 \pi V_{t}\right)^{-\frac{1}{2}} \exp \left(-\frac{\tilde{y}_{t}^{2}}{2 V_{t}}\right) \tag{3.15}
\end{equation*}
$$

where $\tilde{y}_{t}=y_{t}-x(t \mid t-1)$ and $V_{t}=P_{t \mid t-1}+R[13]$. Dropping the constant $2 \pi$, we get

$$
\begin{equation*}
l=-2 \ln L=\sum_{t=1}^{n}\left[\frac{\tilde{y}_{t}^{2}}{V_{t}}+\ln V_{t}\right] . \tag{3.16}
\end{equation*}
$$

From (3.14) we have

$$
P_{t \mid t-1}=G P_{t-1} G^{\prime}+\sigma^{2} A A^{\prime} .
$$

Hence, the variance $\sigma^{2}$ can be removed from the nonlinear estimation problem by dividing $R$ by $\sigma^{2}$. The observational error variance is then replaced by the ratio of
the observational error variance to $\sigma^{2}$. In the recursions, since all variances have the same scale factor, $P_{t \mid t-1}$ and $P_{t \mid t}$ are replaced by $\sigma^{2} P_{t \mid t-1}$ and $\sigma^{2} P_{t \mid t}$, respectively, and the likelihood becomes

$$
\begin{equation*}
l=-2 \ln L=\sum_{t=1}^{n}\left[\frac{\tilde{y}_{t}^{2}}{\sigma^{2} V_{t}}+\ln \left(\sigma^{2} V_{t}\right)\right] \tag{3.17}
\end{equation*}
$$

Differentiating this with respect to $\sigma^{2}$ and equating it to zero gives

$$
\begin{equation*}
\sigma^{2}=\frac{1}{n} \sum_{t=1}^{n} \frac{\tilde{y}_{t}^{2}}{V_{t}} . \tag{3.18}
\end{equation*}
$$

Then substituting into (3.17) and dropping the constants gives

$$
\begin{equation*}
l=n \ln \sum_{t=1}^{n} \frac{\tilde{y}_{t}^{2}}{V_{t}}+\sum_{t=1}^{n} \ln V_{t} \tag{3.19}
\end{equation*}
$$

the function to be minimized with respect to the remaining parameters $\phi_{1}, \cdots, \phi_{p}$, $\psi_{1}, \cdots, \psi_{q}, d$ and $R$.

Jones uses a vector of zeros as initial state vector $\theta_{0}$, as well as the Akaike method to calculate the initial state covariance matrix $P_{0}=P_{0 \mid 0}$ (see [13] for details). If an observation $y_{t+1}$ is missing, $\sigma^{2}$ in (3.17) through (3.19) is set to 1 and estimated later. Equations (3.7) and (3.11) are replaced by

$$
\hat{\theta}_{t+1 \mid t+1}=\hat{\theta}_{t+1 \mid t},
$$

and

$$
P_{t+1 \mid t+1}=P_{t+1 \mid t},
$$

respectively. The corresponding term in (3.19) for the accumulation of $-2 \ln$ likelihood is skipped. If a large block of data is missing, the recursion is equivalent to restarting the recursion at the other end.

Let $x_{t}$ be a time series following an (ARIMA) model with order $(p, d, q)$, i.e.,

$$
\begin{equation*}
\phi(B) \alpha(B) x_{t}=\psi(B) \epsilon_{t}, \quad t=1, \cdots, n \tag{3.20}
\end{equation*}
$$

where n is the number of observations in the time series; $B$ is the backshift operator such that $B x_{t}=x_{t-1} ; \phi(B)=1-\phi_{1} B-\cdots-\phi_{p} B^{p} ; \psi(B)=1-\psi_{1} B-\cdots-\psi_{q} B^{q}$ are polynomials of $B$ with all roots outside the unit circle; and $\alpha(B)=(1-B)^{d}$ with all roots of $\alpha(B)$ on the unit circle. Also, $\left\{\epsilon_{t}\right\}$ is white noise with mean zero and variance $\sigma^{2}$. Notice that $\alpha(B) x_{t}$ satisfy $\operatorname{ARMA}(p, q)$. So we can use a state-space representation for the ARMA model to solve the state-space model for ARIMA model.

### 3.1.2 EM Algorithm

The EM algorithm is a general iterative algorithm for ML estimation in an incomplete data problem [19]. It consists of an Expectation step followed by a Maximization step. The idea is to fill in the missing data $X_{\text {miss }}$ based on an initial estimate of the parameter $\theta$, re-estimate $\theta$ based on $X_{o b s}$ and the filled-in $X_{\text {miss }}$, and iterate until the estimates converge. The specific applications of this idea have appeared in the statistical literature, and go as far back as 1926 [14]. The term EM was introduced by Dempster, Laird and Rubin [7] in 1977. Since then, there have
been many new uses of the EM algorithm, as well as further work on its convergence properties, e.g. Wu (1983) [22], Little and Rubin (1987) [14], Schafer (1997) [19]. In any incomplete data problem, the distribution of the complete data $X$ can be factored as

$$
\begin{equation*}
f(X \mid \theta)=f\left(X_{o b s} \mid \theta\right) f\left(X_{\text {miss }} \mid X_{o b s}, \theta\right) \tag{3.21}
\end{equation*}
$$

Let $l(\theta \mid X)=\ln f(X \mid \theta)$. The corresponding log-likelihood is

$$
\begin{equation*}
l(\theta \mid X)=l\left(\theta \mid X_{o b s}\right)+\ln f\left(X_{m i s s} \mid X_{o b s}, \theta\right) \tag{3.22}
\end{equation*}
$$

Since $X_{\text {miss }}$ is unknown, we take the expectation of (3.22) with respect to the distribution $f\left(X_{m i s s} \mid X_{o b s}, \theta^{t}\right)$, where $\theta^{t}$ is an estimate of the unknown parameter $\theta$. Then we get

$$
\begin{equation*}
Q\left(\theta \mid \theta^{t}\right)=l\left(\theta \mid X_{o b s}\right)+H\left(\theta \mid \theta^{t}\right) \tag{3.23}
\end{equation*}
$$

where

$$
Q\left(\theta \mid \theta^{t}\right)=\int l(\theta \mid X) f\left(X_{m i s s} \mid X_{o b s}, \theta^{t}\right) d X_{m i s s}
$$

and

$$
H\left(\theta \mid \theta^{t}\right)=\int\left[\ln f\left(X_{m i s s} \mid X_{o b s}, \theta\right)\right] f\left(X_{m i s s} \mid X_{o b s}, \theta^{t}\right) d X_{\text {miss }}
$$

Let $\theta^{t+1}$ be the value of $\theta$ that maximizes $Q\left(\theta \mid \theta^{t}\right)$; then

$$
Q\left(\theta^{t+1} \mid \theta^{t}\right) \geq Q\left(\theta^{t} \mid \theta^{t}\right)
$$

By the fact that $\ln x \leq x-1$, we have

$$
\begin{aligned}
H\left(\theta^{t} \mid \theta^{t}\right)-H\left(\theta^{t+1} \mid \theta^{t}\right)= & \int\left[\ln f\left(X_{\text {miss }} \mid X_{o b s}, \theta^{t}\right)\right] f\left(X_{\text {miss }} \mid X_{o b s}, \theta^{t}\right) d X_{\text {miss }} \\
& -\int\left[\ln f\left(X_{\text {miss }} \mid X_{o b s}, \theta^{t+1}\right)\right] f\left(X_{\text {miss }} \mid X_{o b s}, \theta^{t}\right) d X_{\text {miss }} \\
= & -\int\left[\ln \frac{f\left(X_{\text {miss }} \mid X_{o b s}, \theta^{t+1}\right)}{f\left(X_{\text {miss }} \mid X_{o b s}, \theta^{t}\right)}\right] f\left(X_{\text {miss }} \mid X_{o b s}, \theta^{t}\right) d X_{\text {miss }} \\
\geq & -\int\left[\frac{f\left(X_{\text {miss }} \mid X_{o b s}, \theta^{t+1}\right)}{f\left(X_{\text {miss }} \mid X_{o b s}, \theta^{t}\right)}-1\right] f\left(X_{\text {miss }} \mid X_{o b s}, \theta^{t}\right) d X_{\text {miss }} \\
= & -\int\left[f\left(X_{\text {miss }} \mid X_{o b s}, \theta^{t+1}\right)-f\left(X_{\text {miss }} \mid X_{o b s}, \theta^{t}\right)\right] d X_{\text {miss }} \\
= & 0
\end{aligned}
$$

Hence,

$$
\begin{aligned}
l\left(\theta^{t+1} \mid X_{o b s}\right)-l\left(\theta^{t} \mid X_{o b s}\right) & =Q\left(\theta^{t+1} \mid \theta^{t}\right)-H\left(\theta^{t+1} \mid \theta^{t}\right)-\left(Q\left(\theta^{t} \mid \theta^{t}\right)-H\left(\theta^{t} \mid \theta^{t}\right)\right) \\
& =Q\left(\theta^{t+1} \mid \theta^{t}\right)-Q\left(\theta^{t} \mid \theta^{t}\right)+H\left(\theta^{t} \mid \theta^{t}\right)-H\left(\theta^{t+1} \mid \theta^{t}\right) \\
& \geq 0
\end{aligned}
$$

That is,

$$
l\left(\theta^{t+1} \mid X_{o b s}\right) \geq l\left(\theta^{t} \mid X_{o b s}\right)
$$

Thus maximizing $l\left(\theta \mid X_{o b s}\right)$ is sufficed to maximizing $Q\left(\theta \mid \theta^{t}\right)$. One iteration of the EM algorithm includes two steps:

1. E-step: the function $Q\left(\theta \mid \theta^{t}\right)$ is calculated by taking the expectation of $l(\theta \mid X)$ with the distribution $f\left(X_{\text {miss }} \mid X_{o b s}, \theta^{t}\right)$.
2. M-step: the parameter $\theta$ is found by maximizing $Q\left(\theta \mid \theta^{t}\right)$.

The two steps are iterated until the iterations converge. In SAS, the EM algorithm by Schafer [19] is used in the MI procedure. Let the parameter $\theta=(\mu, \Sigma)$. For multivariate normal data, suppose there are $G$ groups with distinct missing patterns. Then the observed-data $\log$-likelihood can be expressed as

$$
l\left(\theta \mid X_{o b s}\right)=\sum_{g=1}^{G} l_{g}\left(\theta \mid X_{o b s}\right)
$$

where $l_{g}\left(\theta \mid X_{o b s}\right)$ is the observed-data log-likelihood from the $g$ th group, and

$$
l_{g}\left(\theta \mid X_{o b s}\right)=-\frac{n_{g}}{2} \ln \left|\Sigma_{g}\right|-\frac{1}{2} \sum_{i g}\left[\left(\mathbf{x}_{i g}-\mu_{g}\right)^{\prime} \Sigma_{g}^{-1}\left(\mathbf{x}_{i g}-\mu_{g}\right)\right]
$$

where $n_{g}$ is the number of observations in the gth group, the summation is over observations in the gth group, $\mathbf{x}_{i g}$ is a vector of observed values of $\mathbf{x}_{g}$ variables, $\mu_{g}$ is the corresponding mean vector, and $\Sigma_{g}$ is the associated covariance matrix. The initial values for the first iteration are the sample means and sample variances from the observed data. The E-step uses the standard sweep operator [14] on the covariance matrix of the observations to calculate the conditional expectation and variance of missing values. Suppose that $A$ is a $(p \times p)$ symmetric matrix with elements $a_{i j}$. The standard sweep operator $S W P[k]$ operates on $A$ by replacing it with another $(p \times p)$ symmetric matrix $B$, where the elements of $B$ are given by

$$
\begin{aligned}
b_{k k} & =-\frac{1}{a_{k k}} \\
b_{j k} & =b_{k j}=\frac{a_{j k}}{a_{k k}} \text { for } k \neq j \\
b_{j l} & =b_{l j}=a_{j l}-\frac{a_{j k} a_{k l}}{a_{k k}} \text { for } k \neq j \text { and } k \neq l
\end{aligned}
$$

Let $B=S W P[k] A$. For example, assume $x_{t}$ is a time series following the model:

$$
\begin{equation*}
(1-\phi B) x_{t}=\mu+\epsilon_{t} \quad \text { for } t=1, \cdots, n \tag{3.24}
\end{equation*}
$$

where $|\phi|<1,\left\{\epsilon_{t}\right\}$ is white noise with mean zero and variance $\sigma^{2}$. Let $\theta=(\mu, \phi, \sigma)$. The ML estimate is $\hat{\theta}=(\hat{\mu}, \hat{\phi}, \hat{\sigma})$. Hence the variance and covariance of missing values can be estimated by $\hat{\theta}$. Suppose that $x_{j}$ is missing, and that $x_{j-1}$ and $x_{j+1}$ are present. The covariance matrix of $x_{j-1}, x_{j}$ and $x_{j+1}$ is

$$
A=\frac{\sigma^{2}}{1-\phi^{2}}\left[\begin{array}{lll}
1 & \phi & \phi^{2} \\
\phi & 1 & \phi \\
\phi^{2} & \phi & 1
\end{array}\right]
$$

Sweeping on $\operatorname{var}\left(x_{j-1}\right)$, i.e. row and column 1, we get

$$
A_{j-1} \equiv S W P[1] A=\left[\begin{array}{ccc}
-\frac{1-\phi^{2}}{\sigma^{2}} & \phi & \phi^{2} \\
\phi & \sigma^{2} & \sigma^{2} \phi \\
\phi^{2} & \sigma^{2} \phi & \sigma^{2}\left(1+\phi^{4}\right)
\end{array}\right]
$$

Then sweeping on $\operatorname{var}\left(x_{j+1}\right)$, i.e. row and column 3,

$$
S W P[3] A_{j-1}=\frac{1}{1+\phi^{2}}\left[\begin{array}{ccc}
-\frac{1}{\sigma^{2}} & \phi & -\frac{\phi^{2}}{\sigma^{2}}  \tag{3.25}\\
\phi & \sigma^{2} & \phi \\
-\frac{\phi^{2}}{\sigma^{2}} & \phi & -\frac{1}{\sigma^{2}}
\end{array}\right]
$$

From (3.25), we get

$$
\operatorname{Var}\left(x_{j} \mid x_{j-1}, x_{j+1}, \theta\right)=\frac{\sigma^{2}}{1+\phi^{2}}
$$

and

$$
\begin{aligned}
E\left(x_{j} \mid x_{j-1}, x_{j+1}, \theta\right) & =\mu+\frac{\phi}{1+\phi^{2}}\left(x_{j-1}-\mu\right)+\frac{\phi}{1+\phi^{2}}\left(x_{j+1}-\mu\right) \\
& =\mu\left(1-\frac{2 \phi}{1+\phi^{2}}\right)+\frac{\phi}{1+\phi^{2}}\left(x_{j-1}+x_{j+1}\right)
\end{aligned}
$$

### 3.2 Outlier Detection

The effects of extraneous objects, device failure and human errors may distort the field data. Usually qualified engineers, scientists or technicians identify abnormalities after inspecting the data manually. This manual process is slow, costly, and sometimes inconsistent among inspectors. Various methods, such as artificial intelligence [8], neural networks [12] and outlier detection in time series models, have been used for detecting abnormal values in data. In this thesis, we use time series analysis to detect and remove the abnormal data.

The effect of an outlier could be either a short-term transient effect or a long-term change. With short-term effects, one or more outliers may be visible in the time series plot and these can create problems for handling non-stationary with standard time series methods. Thus detecting and removing outliers becomes important in modeling. Four types of outliers are usually considered: innovational outlier (IO), additive outlier (AO), level shift (LS) and temporary change (TC) [20]. An IO represents an extraordinary shock at a time point influencing a sequence of points. An AO causes an immediate and one-shot effect on the observed series. A LS produces an abrupt and permanent step change in the series. A TC causes an
initial effect at a time point, and this effect dies out gradually over time. Since any effect on wind speed is short-term, only IO and AO are considered in this thesis. The approach to deal with outliers here is using intervention models to identify the locations and the types of outliers, and to remove the impacts of outliers.

### 3.2.1 Estimates of Outlier Impacts and Hypothesis Testing

Let $x_{t}$ be a time series following an autoregressive-integrated-moving average (ARIMA) model with order $(p, d, q)$; that is,

$$
\begin{equation*}
\phi(B) \alpha(B) x_{t}=\psi(B) \epsilon_{t}, \quad t=1, \cdots, n \tag{3.26}
\end{equation*}
$$

where n is the number of observations in the time series; $B$ is the backshift operator such that $B x_{t}=x_{t-1} ; \phi(B)=1-\phi_{1} B-\cdots-\phi_{p} B^{p}$ and $\psi(B)=1-\psi_{1} B-\cdots-\psi_{q} B^{q}$ are polynomials of $B$ with all roots outside the unit circle; $\alpha(B)=(1-B)^{d}$ with all roots of $\alpha(B)$ on the unit circle; and $\left\{\epsilon_{t}\right\}$ are independent and identically normal distributed with mean zero and variance $\sigma^{2}$. We consider the estimation problem when both the location and the dynamic pattern of an outlier are not known. The approach is to classify an outlier impact into two types: IO and AO.

If the location and the dynamic pattern of an event are known, then the models [1] are:

$$
\begin{array}{ll}
I O: & z_{t}=\frac{\psi(B)}{\phi(B) \alpha(B)}\left(\epsilon_{t}+\omega \zeta_{t}^{(T)}\right) \text { and }  \tag{3.27}\\
A O: & z_{t}=\frac{\psi(B)}{\phi(B) \alpha(B)} \epsilon_{t}+\omega \zeta_{t}^{(T)}
\end{array}
$$

where $B, \phi(B), \psi(B), \alpha(B)$ and $\left\{\epsilon_{t}\right\}$ are the same as in model (3.12), $\omega$ is the impact of the possibly unknown outlier at $T$, and

$$
\zeta_{t}^{T}= \begin{cases}1 & \text { for } t=T \\ 0 & \text { otherwise }\end{cases}
$$

and indicates the time of occurrence of the outlier impact. Here $T$ is the possibly unknown location of the outlier. Then (3.27) can be written in the form

$$
\begin{align*}
& I O: \quad z_{t}=x_{t}+\frac{\psi(B)}{\phi(B) \alpha(B)} \omega \zeta_{t}^{(T)}  \tag{3.28}\\
& A O: \\
& z_{t}=x_{t}+\omega \zeta_{t}^{(T)} .
\end{align*}
$$

The effect of an IO is more intricate than the effects of other types of outliers. An IO represents an extraordinary shock at time point $T$ influencing $z_{T}, z_{T+1}, \cdots$, through the dynamic system described by $\frac{\psi(B)}{\phi(B) \alpha(B)}$. To examine the effects of outliers on the estimated residuals in model (3.12), we assume that the time series parameters are known and the series is observed from $t=-J$ to $t=n$, where $J$ is an integer larger than $p+d+q$, and $1 \leq T \leq n$. Let $\pi(B)=\frac{\phi(B) \alpha(B)}{\psi(B)}=1-\pi_{1} B-\pi_{2} B^{2}-\cdots$. Because the zeros of $\psi(B)$ are all outside the unit circle, the weights $\pi_{j}$ 's for $j$ beyond $J$ would in practice become essentially equal to zero with $J$ of moderate size. We use the outlier contaminated data $\left\{z_{t}\right\}$ for model (3.12) to get the estimated residual $\hat{e}_{t}=\hat{\pi}(B) z_{t}$ for $t=1, \cdots, n$. For our two types of outliers, from (3.27) we have

$$
\begin{array}{ll}
I O: & \hat{e}_{t}=\omega \zeta_{t}^{(T)}+\epsilon_{t} \text { and }  \tag{3.29}\\
A O: & \hat{e}_{t}=\omega \hat{\pi}(B) \zeta_{t}^{(T)}+\epsilon_{t}
\end{array}
$$

where $\hat{\pi}(B)=\pi_{\hat{\psi}}(B)$ and $\hat{\psi}$ is MLE of $\psi$ in (3.12) [2]. From the theory of least squares, the estimators of the impact $\omega$ in these two models are

$$
\begin{array}{ll}
I O: & \hat{\omega}_{I O}=\hat{e}_{T} \text { and }  \tag{3.30}\\
A O: & \hat{\omega}_{A O}=\hat{\rho}^{2} \hat{\pi}(F) \hat{e}_{T}=\hat{\rho}^{2} \hat{\pi}(F) \hat{\pi}(B) z_{T},
\end{array}
$$

where $\hat{\rho}^{2}=\left(1+\hat{\pi}_{1}^{2}+\hat{\pi}_{2}^{2}+\cdots+\hat{\pi}_{n-T}^{2}\right)^{-1}$ and $F$ is the forward-shift operator. Let $H_{0}$ be the null hypothesis that $\omega=0$ at $T, H_{I O}$ be the alternative hypothesis that an IO exists at $T$, and $H_{A O}$ be the alternative hypothesis that an AO exists at $T$. From (3.12) and (3.28), the variances of the estimators for the impacts under $H_{0}$ are the following:

$$
\begin{array}{ll}
I O: & \operatorname{var}\left(\hat{\omega}_{I O}\right)=\sigma^{2} \\
A O: & \operatorname{var}\left(\hat{\omega}_{A O}\right)=\rho^{2} \sigma^{2} .
\end{array}
$$

Noticing $\mathbf{E} \hat{\omega}_{I O}=\mathbf{E} \hat{\omega}_{A O}=0\left(\mathbf{E}\right.$ means expectation under $\left.H_{0}\right)$, hence the results can be used to construct test statistics for testing the existence of an outlier. Thus the likelihood ratio tests are:

$$
\begin{array}{ll}
H_{0} \text { vs } H_{I O}: & \hat{\lambda}_{I O, T}=\frac{\hat{\omega}_{I O}}{\hat{\sigma}} \text { and }  \tag{3.31}\\
H_{0} \text { vs } H_{A O}: & \hat{\lambda}_{A O, T}=\frac{\hat{\omega}_{A O}}{\hat{\sigma} \hat{\sigma}},
\end{array}
$$

where $\hat{\sigma}=1.483 \times$ median $\left\{\left|\hat{e}_{t}-\tilde{e}\right|\right\}$, and $\tilde{e}$ is the median of the estimated residuals [6]. The standardized statistics of the outlier effects $\hat{\lambda}_{I O, T}$ and $\hat{\lambda}_{A O, T}$ in (3.31) asymptotically have a standard normal distribution [4].

To locate an IO or AO, the following decision rules are used:

$$
\begin{equation*}
I O: \hat{\eta}_{I O}=\max _{1 \leq T \leq n}\left|\hat{\lambda}_{I O, T}\right|>c \tag{3.32}
\end{equation*}
$$

Figure 3.2: Flow Chart for the Procedure of Outlier Detection

$$
\begin{equation*}
A O: \quad \hat{\eta}_{A O}=\max _{1 \leq T \leq n}\left|\hat{\lambda}_{A O, T}\right|>c \tag{3.33}
\end{equation*}
$$

where $c$ is some suitably chosen positive constant. In practice, it is recommended to use $c=3.0$ for high sensitivity, $c=3.5$ for medium sensitivity, and $c=4.0$ for low sensitivity in the outlier-detecting procedure when the length of the series is less than 200 [4]. In this thesis $c=3.5$ is chosen to detect the outliers at any suspected point $T$. The possible outlier is classified as an IO if $\left|\hat{\lambda}_{I O, T}\right|>\left|\hat{\lambda}_{A O, T}\right|$, else it is classified as an AO.

### 3.2.2 Outlier Detection Algorithm

The procedure for detecting outliers is described as follows (the flow chart is shown in Figure 3.2):

1. Estimate ARIMA model (3.26) using $\left\{z_{t}\right\}$ and compute the residuals $\hat{e}_{t}$ to get $\hat{\omega}_{I O}$ and $\hat{\omega}_{A O}$.
2. Find the median of the residuals $\tilde{e}$, and use $\hat{\sigma}=1.483 \times \operatorname{median}\left\{\mid \hat{e}_{t}-\right.$ $\tilde{e} \mid\}$ as the estimate of $\sigma$. Compute $\hat{\lambda}_{I O, t}$ and $\hat{\lambda}_{A O, t}$ for $t=1, \cdots, n$. Let $\eta_{t}=$ $\max \left\{\left|\hat{\lambda}_{I O, t}\right|,\left|\hat{\lambda}_{A O, t}\right|\right\}$ for $t=1, \cdots, n$. Record the location $\tau_{t}=t$ if $\eta_{t}>3.5$, else $\tau_{t}=$ 0. If $\sum_{i=1}^{n} \tau_{i}=0$, stop. If $\eta=\max _{t} \eta_{t}=\left|\hat{\lambda}_{I O, T}\right|>3.5$, then there is the possibility of an IO at $T$. The impact $\omega$ is estimated by $\hat{\omega}_{I O}$ in (3.30). If $\eta=\max _{t} \eta_{t}=\left|\hat{\lambda}_{A O, T}\right|>3.5$, then there is the possibility of an AO at $T$. The impact $\omega$ is estimated by $\hat{\omega}_{A O}$ in (3.30).
3. For the point $T$ in step 2 , the new residual for $I O$ is set to

$$
\check{e}_{t}= \begin{cases}0, & \text { for } t=T \\ \hat{e}_{t}, & \text { else }\end{cases}
$$

The new residuals adjusting for AO are

$$
\check{e}_{t}= \begin{cases}\hat{e}_{t}, & \text { for } t<T \\ \hat{e}_{t}-\hat{\omega}_{A O} \hat{\pi}(B) \zeta_{t}^{(T)} & \text { for } t \geq T\end{cases}
$$

A new estimate $\check{\sigma}$ is computed from the modified residuals. Recompute $\hat{\omega}_{I O}, \hat{\omega}_{A O}, \hat{\lambda}_{I O, t}$ and $\hat{\lambda}_{A O, t}$ based on the same initial estimates of the time series parameters, but using the modified residuals $\check{e}_{t}$ 's and the estimate $\check{\sigma}$.
4. Repeat steps 2 and 3 until no further outlier candidates can be identified, that is, $\sum_{i=1}^{n} \tau_{i}=0$.
5. Suppose that the $k$ time points $T_{1}, \cdots, T_{k}$ are detected as IO's or AO's.

Treat these times as known, and estimate the outlier parameters $\omega_{1}, \omega_{2}, \cdots, \omega_{k}$ and the time series parameters simultaneously, using models of the form

$$
\begin{equation*}
z_{t}=\sum_{i=1}^{k} \omega_{i} L_{i}(B) \zeta_{t}^{\left(T_{t}\right)}+\frac{\psi(B)}{\phi(B) \alpha(B)} \epsilon_{t} \tag{3.34}
\end{equation*}
$$

where

$$
L_{i}(B)= \begin{cases}1 & \text { for an AO at } t=T_{i} \\ \frac{\psi(B)}{\phi(B) \alpha(B)} & \text { for an IO at } t=T_{i}\end{cases}
$$

6. Repeat step 1 to 5 until no further new outlier is detected.

### 3.2.3 Outlier Detection with Missing Values

Before detecting outliers, we first impute missing values. In this section, three imputation methods are used: nearby window average imputation, Jones imputation using Kalman filter [13] and EM algorithm imputation [19]. We study the power of these three imputation methods by using a small portion of time series from station L001. Three data sets are used. Data set A (True) is the hourly wind speed data of January 1996 without missing values. Data sets B and D are constructed from the data set $A$ with missing values by deleting some observations and then imputing these missing values using the EM and Jones imputation, respectively. The locations of missing values are listed in Table 3.1. Data set C is constructed from the data set A with missing values by deleting some observations and imputing these missing values using nearby window average imputation. The average value is the average

Table 3.1: Location of Missing Values

| Beginning | End | Number of missing |
| ---: | ---: | ---: |
| 03JAN96:12 | 03JAN96:13 | 2 |
| 19JAN96:04 | 19JAN96:06 | 3 |
| 23JAN96:13 | 23JAN96:17 | 5 |
| 25JAN96:16 | 26JAN96:05 | 14 |

of one value before the missing value begins and one value after the missing value ends. To fit the models for the data, we use the Time Series Forecasting System in SAS. The system can generate the best model by using 12 criteria such as Mean square error, R-square, Akaike Information criterion (AIC), and Schwarz Bayesian Information Criterion (SBC). Here we use AIC and SBC. For ARIMA models, AIC and SBC are computed as follows:

$$
\begin{aligned}
& A I C:-2 \ln (L)+2 k \text { and } \\
& S B C:-2 \ln (L)+k \ln (n),
\end{aligned}
$$

where $L$ is the likelihood function, $k$ is the number of free parameters and $n$ is the number of residuals that can be computed for the time series. For the exponential models, AIC and SBC are computed as follows:

$$
\begin{aligned}
& A I C: n \ln \left(\frac{S S E}{n}\right)+2 k \text { and } \\
& S B C: n \ln \left(\frac{S S E}{n}\right)+k \ln (n)
\end{aligned}
$$

where $S S E=\sum_{t=0}^{n}\left(y_{t}-\hat{y}_{t}\right)^{2}$, and $\hat{y}_{t}$ is the one-step predicted value for the series. The smaller the values of AIC and SBC are, the better the model is. By comparing
the values of AIC and SBC for several possible models for these three data sets, we choose single exponential smoothing models. The single exponential smoothing model in SAS is defined as follows [16]: Let $x_{t}$ be a time series observation at period $t$. The single exponential smoothing operation is

$$
\begin{equation*}
s_{t}=\alpha x_{t}+(1-\alpha) s_{t-1} \tag{3.35}
\end{equation*}
$$

and

$$
\begin{equation*}
\hat{x}_{t+1}=s_{t}, \tag{3.36}
\end{equation*}
$$

where $s_{t}$ is the smoothed value at period $t, \alpha$ is the smoothing constant $(0<\alpha<1)$, and $F_{t+1}$ is the forecast for $x_{t+1}$. Thus (3.36) can be rewritten as

$$
\begin{align*}
\hat{x}_{t+1} & =\alpha x_{t}+(1-\alpha) \hat{x}_{t}  \tag{3.37}\\
& =\alpha\left[x_{t}+(1-\alpha) x_{t-1}+(1-\alpha)^{2} x_{t-2}+\cdots\right] \tag{3.38}
\end{align*}
$$

Theorem The single exponential smoothing model is equivalent to the
$\operatorname{ARIMA}(0,1,1)$ model [5].

## Proof:

Let $x_{t}$ be a time series following ARIMA( $0,1,1$ ) model, that is

$$
\begin{equation*}
(1-B) x_{t}=(1-\psi B) \epsilon_{t} \quad t=1, \cdots, n \tag{3.39}
\end{equation*}
$$

where $n, B, \psi$ and $\epsilon_{t}$ are the same as model (3.12). Rewrite (3.39) as:

$$
\begin{equation*}
x_{t}-x_{t-1}=\epsilon_{t}-\psi \epsilon_{t-1} \tag{3.40}
\end{equation*}
$$

or

$$
\begin{equation*}
\epsilon_{t}=x_{t}-x_{t-1}+\psi \epsilon_{t-1} \tag{3.41}
\end{equation*}
$$

Then we have

$$
\begin{equation*}
x_{t}=x_{t-1}+\epsilon_{t}-\psi \epsilon_{t-1}=x_{t-1}-\psi \epsilon_{t-1}+\epsilon_{t} . \tag{3.42}
\end{equation*}
$$

Therefore, the one-step-ahead forecast for $x_{n+1}$ based on $x_{1}, \cdots, x_{n}$ is

$$
\begin{equation*}
\hat{x}_{n+1}=x_{n}-\psi \epsilon_{n} \tag{3.43}
\end{equation*}
$$

From (3.41) and (3.43), we have

$$
\begin{aligned}
\hat{x}_{n+1} & =x_{n}-\psi\left(x_{n}-x_{n-1}+\psi \epsilon_{n-1}\right) \\
& =x_{n}-\psi\left(x_{n}-\hat{x}_{n}-\psi \epsilon_{n-1}+\psi \epsilon_{n-1}\right) \\
& =x_{n}-\psi\left(x_{n}-\hat{x}_{n}\right) \\
& =x_{n}-\psi x_{n}+\psi \hat{x}_{n} \\
& =(1-\psi) x_{n}+\psi \hat{x}_{n} .
\end{aligned}
$$

Setting $\alpha=1-\psi$, the above equation is the same as (3.35).
Let $\epsilon_{t}=x_{t}-\hat{x}_{t}$ for all $t$. Then $\hat{x}_{t}=x_{t}-\epsilon_{t}$. From (3.37), we have

$$
\begin{aligned}
x_{t+1}-\epsilon_{t+1} & =\alpha x_{t}+(1-\alpha)\left(x_{t}-\epsilon_{t}\right) \\
x_{t+1}-\epsilon_{t+1} & =\alpha x_{t}+x_{t}-\alpha x_{t}-(1-\alpha) \epsilon_{t} \\
x_{t+1}-x_{t} & =\epsilon_{t+1}-(1-\alpha) \epsilon_{t} \\
(1-B) x_{t+1} & =(1-(1-\alpha) B) \epsilon_{t+1} .
\end{aligned}
$$

Table 3.2: Summary of Outlier Detection

Table 3.3: Classification Matrix

| Type | Data B |  | Data C |  |  | Data D |  |  | Total |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | AO IO | * | AO | IO | * | AO | IO |  |  |
| AO | 100 | 2 | 11 | 1 | 0 | 11 |  | 0 | 12 |
| IO | 026 | 1 | 0 | 26 | 1 | 0 | 26 | 1 | 27 |
| * | 04 | 57 | 10 | 232 | 28 | 8 | 45 | 8 | 61 |
| Total | 1030 | 60 | 21 | 502 | 29 | 19 | 72 | 9 | 100 |

Setting $\psi=1-\alpha$, the above equation is the same as (3.39).
Thus, the ARIMA( $0,1,1$ ) model is used for outlier detection. Table 3.2 lists the locations, impacts and types of outliers that are detected in the four data sets. Given data A are true, from Table 3.3, the overall correct rates of outliers (IO,AO and over detected outliers labeled by ${ }^{*}$ ) of data B, C and D are $\frac{10+26+57}{100}=93 \%$, $\frac{11+26+29}{100}=66 \%$ and $\frac{11+26+8}{100}=45 \%$, respectively, while the correct rates of outliers $(\mathrm{IO}, \mathrm{AO})$ of data B, C and D are $\frac{10+26}{12+27}=92 \%, \frac{11+1+26}{12+27}=97 \%$ and $\frac{11+1+26}{12+27}=97 \%$, respectively; the correct rates of IO outliers of all three methods are $\frac{26}{27}=96 \%$; the correct rates of AO outliers of data B is $\frac{10}{12}=83 \%$; the correct rates of AO outliers of data C and D are $\frac{11}{12}=92 \%$.

By comparing the correction rates, we see that the best result is the EM algorithm. We also know that when the data are not fully observed, the EM algorithm is a general technique for finding maximum-liklihood estimates for parametric models [19]. Hence we use the EM algorithm to fill the missing values and then detect outliers for the data set in this thesis.

## Chapter 4

## MODELING

To get the best model for the wind speed data, we use EM algorithm to impute missing values and the method introduced in Chapter 3 to detect outliers and remove impacts of outliers. Let $x_{t}$ be the true time series, $y_{t}$ be the observed series with missing values and outliers, and $z_{t}$ be the observed series with outliers after imputation. The idea is the following (Figure 4.1):

Step 1: Impute the missing values in $y_{t}$ using the EM algorithm. The data set we get then is $z_{t}$. SAS code is in Appendix A.1.

Step 2: Detect outliers and remove the impacts of outliers in $z_{t}$. The data set we get then is $x_{t}$.

Step 3: Let $y_{t}^{\prime}$ be $x_{t}$ but with the same missing values as $y_{t}$. Re-do steps 1 and 2. If there exist outliers in step 2, finish step 2 and do step 3. Otherwise, fit the best models for $z_{t}$.

The data set used in this chapter is the hourly wind speeds of all four stations from May to August in 2000. To fit the models for the data, we still use Time Series Forecasting System in SAS. AIC and SBC are used as information criterions. During

Figure 4.1: Flow Chart of Modeling Process
the process of imputing missing values, detecting outliers and removing impacts of outliers, we get the fitted models are seasonal ARIMA models. In SAS, the seasonal ARIMA model is denoted by $\operatorname{ARIMA}(p, d, q) \times(P, D, Q)_{s}$. The term $(p, d, q)$ gives the order of the nonseasonal part of the ARIMA model; the term $(P, D, Q)_{s}$ gives the order of the seasonal part. The value of $s$ is the number of observations in a seasonal cycle such as 12 for monthly series. The fitted models are ARIMA(2, 0, 0) $\times(1,0,0)_{24}$ of the form

$$
\left(1-\phi_{1,1} B-\phi_{1,2} B^{2}\right)\left(1-\phi_{2,1} B^{24}\right) x_{t}=\mu+\epsilon_{t} .
$$

For convenience of outlier detection stage, we de-mean before fitting the models.
Table 4.1 reports the summary of outer loops in outlier detection stage in the first

Table 4.1: Outlier Detection Report

| Outer | L001 |  | L005 |  |  | L006 |  |  | LZ40 |  |  |
| ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: |

| 2 |  |  |  |  |  |  |  |  |  |  |  |
| 6 |  |  |  | 10.007 | 0 | 4 | 9.691 | 2 | 1 | 9.938 | 2 |
| 7 |  |  |  | 10.006 | 0 | 3 | 9.687 | 1 | 0 | 9.942 | 1 |

loop of modeling. In the second loop of modeling, no outlier is detected in Station L001, L005 and LZ40. Hence we go on to model for Station L006 until no outlier is detected in the locations of observed values. Finally, after imputing missing values, and detecting and removing impacts of outliers, we get the following best models for the hourly wind speeds of stations L001, L005, L006 and LZ40 from May to August in 2000:

$$
\begin{aligned}
& \text { L001: } \quad\left(1-0.895 B+0.097 B^{2}\right)\left(1-0.156 B^{24}\right) x_{t}=10.144+\epsilon_{t} . \\
& \text { L005: } \quad\left(1-0.924 B+0.100 B^{2}\right)\left(1-0.207 B^{24}\right) x_{t}=10.014+\epsilon_{t} . \\
& \text { L006: } \quad\left(1-0.878 B+0.050 B^{2}\right)\left(1-0.240 B^{24}\right) x_{t}=9.659+\epsilon_{t} . \\
& \text { LZ40: } \quad\left(1-0.988 B+0.146 B^{2}\right)\left(1-0.225 B^{24}\right) x_{t}=9.991+\epsilon_{t} .
\end{aligned}
$$

The parameter estimates and goodness of fit tests are shown in Table 4.2. We can see that all the parameter estimates are significant. To check the white-noise assumption, we draw the histograms for residuals. The histograms in Figure 4.2 are about normal. This means that the assumptions for residuals of the four models are

Table 4.2: Parameter Estimates and Good-fitness Tests

|  | p -value | $<0.001$ | $<0.001$ | $<0.001$ | $<0.001$ |
| $\phi_{1,2}$ | estimate | -0.097 | -0.100 | -0.050 | -0.146 |
|  | T | -5.290 | -5.463 | -2.685 | -7.990 |
|  | p-value | $<0.001$ | $<0.001$ | $<0.007$ | $<0.001$ |
| $\phi_{2,1}$ | estimate | 0.156 | 0.207 | 0.240 | 0.225 |
|  | T | 8.517 | 11.388 | 13.236 | 12.375 |
|  | p -value | $<0.001$ | $<0.001$ | $<0.001$ | $<0.001$ |
| AIC |  | 4545.242 | 4291.438 | 4650.076 | 4075.418 |
| SBC |  | 4569.203 | 4315.399 | 4674.036 | 4099.379 |

valid. From the four models, we can conclude that the wind speeds in these four stations have the similar patterns. This conclusion is the same as the one we get in Chapter 2. The first plot in Figure 4.3 is the plot of wind speeds vs time for station L006 from August 14 to 23, 2000. We can see that there is a large block of missing values. The second plot is the plots of wind speed for station L001, L005, LZ40 and imputation wind speeds of L006 at the same time. Again we can see that the plots have similiar patterns. This means that EM algorithm is a very good method to impute missing values for our wind speed data set. We also can see that there is a daily cycle in wind speed data from the models.

Through analyzing of Lake Okeechobee wind speed data, we can conclude that the wind speeds of the four stations we study have similar patterns and a daily

L005

Figure 4.2: Histograms of Residuals

Figure 4.2: Histograms of Residuals

Figure 4.3: Plots of Wind Speeds
cycle. For the data we study in this thesis, the best method to impute missing values is the EM algorithm and the best fitted model is the seasonal $\operatorname{ARIMA}(2,0,0) \times$ $(1,0,0)_{24}$. The fact that the wind speeds of the four stations have similar patterns and models shows that the wind speed in all stations under study behave in a similar way. Furthermore the method of outlier detection using intervention models in time series models and the EM algorithm to impute missing values are more effective
than the manual process of inspecting abnormal values and filling missing values in the data set.

## Chapter 5

## CONCLUSIONS

In this thesis, we analyzed wind speeds at four stations in Lake Okeechobee. There are lots of missing values and outliers in the data. The patterns of wind speeds for all four stations are similar and have a daily cycle. But the monthly means of wind speeds at station L001 are substantially different from those of the other stations in February 1998 and in 1995. This little difference at station L001 may be caused by various reasons such as location of the station, device failures or bird interruptions. Further study is needed. The wind speeds of the stations are correlated positively. A three-parameter Weibull distribution does not fit the data well. The EM algorithm is good for imputing missing values of the data. The method of outlier detection seems more effective than the manual process of inspecting abnormal values and filling missing values in the data set. In a future study, we may consider using a lognormal, beta or mixed distribution to fit the data. We also need combine the computer programs only using SAS.
